Abstract

A new gauge fixing condition is discussed, which is (lattice) rotation invariant, has the ‘smoothness’ properties of the Landau gauge but can be efficiently computed and is unambiguous for almost all lattice gauge field configurations.

Introduction

In gauge theories gauge fixing is necessary to make the perturbation expansion well defined. One of the advantages of the lattice regularization of gauge theories, compared to the continuum formulation, is that gauge fixing on the lattice is not necessary. This is true if only gauge invariant operators are considered. In a growing number of cases, however, it is found advantageous to also use gauge variant operators which makes it necessary to fix the gauge even on the lattice.

For instance, it is interesting to study the gauge variant propagators of quarks and gluons [1]. Also when one wants to compare with gauge dependent results from perturbation theory gauge fixing on the lattice is necessary. In other applications one leaves out the strings of gauge parallel transporters that make operators gauge invariant, like in point split fermion bilinears or extended glueball operators. Since this eliminates the fluctuations of the gauge fields contained in the string, it significantly improves the signal to noise ratio in a Monte Carlo experiment [2]. To restore gauge invariance one must now fix to some uniquely defined gauge. Popular choices are the Landau or Coulomb gauge. An alternative picture justifying this strategy of leaving out parallel transporters is that by fixing to the Coulomb gauge, one dresses the bare charge with its physical gauge boson cloud instead of squeezing this cloud through a connecting flux string. For noncompact QED this interpretation of the Coulomb gauge in terms of a photon cloud can be substantiated [3, 4].

Let us consider the non-gauge fixed gauge field $U_\mu(x) \in G$ with gauge group $G = SU(n)$ or $U(n)$. Suppose the gauge fixed configuration minimizes a (gauge dependent) function $R(U)$. An example is the lattice Landau gauge fixing condition, where

$$R(U) = \text{Re} \sum_{x,\mu} [1 - \frac{1}{n} \text{tr}(U_\mu(x))]. \quad (1)$$

The gauge fixing algorithm should provide the transformation Ω such that $R(U^\Omega)$ assumes its minimal value, where

$$U_\mu^\Omega(x) = \Omega(x) U_\mu(x) \Omega(x + \hat{\mu})^\dagger. \quad (2)$$

If the starting configuration is gauge transformed with g , it should find the transformed

$$\Omega^g(x) = g_0 \Omega(x) g(x)^\dagger, \quad \Omega^g(x)^\dagger = g(x) \Omega^\dagger(x) g_0^\dagger, \quad (3)$$

where the global gauge transformation g_0 need not be fixed. The algorithm should find a unique solution. This means that for all gauge equivalent initial configurations, it should find the same gauge fixed configuration (up to a global gauge transformation g_0). It is clear that this is impossible in principle if the absolute minimum of R is degenerate. But if this would be the only source of ambiguity, one would argue that such an exact degeneracy is an exceptional situation which will not occur in practice. However, finding the absolute minimum of R is extremely difficult and iterative minimalization procedures usually run into some local minimum. Finding the absolute minimum is a numerical problem of non-polynomial complexity.

In the continuum limit, the local minima of R correspond to solutions of the differential Landau condition and the existence of multiple solutions was first discussed by Gribov [5]. Also on the lattice we shall call gauge fields for which R has a (local) minimum Gribov copies. The existence of Gribov copies on the lattice is demonstrated in [6, 7].

In order to remove the Gribov ambiguity it has been proposed to first fix to a uniquely defined axial gauge [8]. But even if the starting gauge field is unique, one can still run into different local minima by using different gauge fixing algorithms. Moreover the axial gauge breaks rotation invariance, and some effect of this might be present in the local minimum that is favored by this particular starting configuration.

Another approach to remove the ambiguity is to include in the gauge fixing condition the requirement of averaging over all initial gauge transformations, such that one averages over a large number of local minima. In practice this procedure is too expensive. Furthermore it is to be expected that the set of local minima that will be found depends on the algorithm used, e.g. it may be different for local algorithms and for non-local ones like multigrid [9]. Finally, averaging over many local minima re-introduces noise in gauge variant operators [6].

In the following we shall discuss a gauge fixing condition which can be computed efficiently and unambiguously for all but a set of exceptional configurations. It shares desirable properties, like smoothness of the gauge fixed configuration, with the Landau-like gauges. Of course, it should be noted that we are not solving the Gribov problem for the usual, local, Landau and Coulomb gauge. We avoid the problem by constructing a modified gauge condition which is no longer local. Because of this non-locality it is not clear if our gauge fixing condition is well suited for perturbative calculations. If not, this will complicate a comparison of gauge dependent results from perturbation theory with nonperturbative lattice calculations. Unlike axial gauges our gauge fixing does not violate global symmetries like e.g. rotation invariance. Therefore it is well suited for the construction of improved interpolating fields for hadrons. To project on a definite symmetry sector of the physical Hilbert space it is essential that the hadron operators transform appropriately under the various global symmetries. It should be noted that the transfer matrix formalism requires the operators to be well localized in euclidean time. This suggests to fix to Coulomb- (rather than Landau-) like gauges when one has this application in mind.

Laplacian gauge fixing

For a given gauge field configuration, we want to find a gauge transformation $\Omega \in G$ which transforms as in (3) and captures the physical ‘smoothness’ of the gauge configurations. Relaxing the property that $\Omega \in G$, the above requirements are reminiscent of finding covariant renormalization group transformations or multigrid blocking kernels and this may suggest to consider eigenfunctions of the gauge covariant laplacian $\Delta(U)$ as in [10, 11, 12]. The covariant laplacian (up to a minus sign) is defined by

$$\Delta(U)(x, y)^{ab} := \sum_{\mu} [2\delta(x - y)\delta^{ab} - U_{\mu}(x)^{ab}\delta(x + \hat{\mu} - y) - U_{\mu}(y)^{\dagger ab}\delta(y + \hat{\mu} - x)] \quad (4)$$

and it is a positive (semi) definite operator. We consider a finite lattice with lattice spacing $a = 1$ and with periodic boundary conditions. The eigenfunctions f^s of $\Delta(U)$ are defined by

$$\Delta(U)(x, y)^{ab} f(y)_b^s = \lambda^s f(x)_a^s, \quad (5)$$

where the $\lambda^s \geq 0$ are the eigenvalues. We shall often suppress a summation over repeated indices. For a non-degenerate spectrum, these eigenfunctions are unique up to a global phase,

$$f(x)_a^s \rightarrow \exp(i\eta^s) f(x)_a^s. \quad (6)$$

Under gauge transformations $U \rightarrow U^g$ the eigenfunctions transform as $f(x)_a^s \rightarrow g(x)^{ab} f(x)_b^s$. This implies that the $GL(n)$ matrix field

$$M(x)^{ab} := f(x)_a^b \quad (7)$$

has the same transformation behavior as gauge transformations $\Omega(x)^{\dagger ab}$, cf.(3). The index b in (7) labels a set of n eigenfunctions. The transformation behavior of M does not depend on which n eigenfunctions we choose, but in order to select the smooth modes in the gauge field, we shall choose the eigenfunctions with the lowest n eigenvalues. This is in the spirit of refs. [10, 11, 12] and will be discussed further below.

In general the matrices $M(x)^{ab}$ are not yet in the gauge group G . However, almost all M can be uniquely decomposed as $M = \Omega^\dagger R$ with $\Omega \in G$ and transforming as in (3). To see this for the case of $G = SU(n)$, we first write $M = WP$ with W a unitary matrix and P a positive hermitian matrix. This decomposition is unique if

$$P = (M^\dagger M)^{1/2} = S^\dagger \text{diag}(\mu_1^{1/2}, \dots, \mu_n^{1/2}) S \quad (8)$$

is invertible, i.e. if M has a non-zero determinant. The unitary matrix S in (8) diagonalizes $M^\dagger M$ and the μ_a are the eigenvalues. Then $W = MP^{-1}$ and $\Omega^\dagger = W \exp(-i\alpha)$ with $\exp i\alpha = \text{diag}(\det(W)^{1/n}, \dots, \det(W)^{1/n})$. If the gauge group is $U(n)$ the determinant need not be factored out.

More explicitly we define the gauge transformation Ω leading to our Laplacian gauge by

$$\Omega_\Delta(x)^{\dagger ab} = f(x)_a^c (P(x)^{-1})^{cb} e^{-i\alpha(x)}. \quad (9)$$

It is clear from the construction that this Ω_Δ indeed transforms as in (3), whereas P and α are invariant.

The global $U(1)$ transformations of the eigenfunctions (6) induce global abelian transformations of Ω_Δ . This follows from the observation that $M^{ab} \rightarrow M^{ab} \exp(i\eta^b)$ implies that $S^{ab} \rightarrow \exp(-i\eta^a) S^{ab} \exp(i\eta^b)$ and consequently $P^{ab} \rightarrow \exp(-i\eta^a) P^{ab} \exp(i\eta^b)$ as well. From (9) it then follows that

$$\Omega_\Delta(x)^{ab} \rightarrow \exp(-i\eta^a - \bar{\eta}) \Omega_\Delta(x)^{ab}, \quad (10)$$

where $\bar{\eta} = \sum_a \eta^a / n$.

In general there is no global $SU(n)$ invariance, only if the lowest n eigenvalues are degenerate one can show along similar lines as above, that a global $SU(n)$ invariance is present.

Singularities and ambiguities

The construction of Ω_Δ outlined above is unambiguous for almost all gauge field configurations: For a given gauge field U the spectrum of $\Delta(U)$ is invariant under gauge transformations g and if the spectrum is non-degenerate, the eigenvalues provide an unambiguous labeling of the eigenfunctions from which the Ω_Δ 's are constructed. In particular, the n eigenfunctions with the lowest eigenvalues can then be computed unambiguously (up to a global phase). The subsequent decomposition works if $\det(M(x)) \neq 0$ for all x .

It is clear from this resumé that there are two sources of ambiguity in our construction. If the $(n+1)$ -th eigenvalue is degenerate with the n -th (labeling them in ascending order), the prescription to take the 'lowest n ' is not well-defined. This means that $\Omega_\Delta(U)$ becomes ambiguous at those points in configuration space, where level n and $n+1$ cross. The level crossing condition fixes one degree of freedom. Hence the singular manifold is of co-dimension one. The second source of ambiguity is at points in configuration space where one or more of the $\det(M(U))$ become zero. The condition that the complex determinant vanishes at some point x fixes two degrees of freedom and hence the singular manifold is of co-dimension two. In addition, for $SU(n)$ the determinant has to be factored out. This requires to take the n -th root of it, which is well-defined only if the determinant is not negative real. This excludes a singular manifold of co-dimension one. In the continuum limit it is expected that these singular sub-manifolds become Gribov horizons giving configuration space the required non-trivial topology to incorporate flux sectors and θ vacua [13].

This discussion shows that the probability to find singular configurations in Monte Carlo simulations on a finite lattice is zero and our gauge fixing condition is unambiguous for all practical purposes.

Relation to the Landau gauge

It is an important property of the Landau gauge that the gauge fixed configuration is smooth in the sense that the link field $U_\mu(x)$ has similar fluctuations as the gauge invariant plaquette field. Of course there will be localized fluctuations as well as obstructions due to nontrivial topology (instantons), but on the average U is close to one if the average plaquette is close to one. By constructing gauge transformations from the eigenfunctions of the covariant laplacian and selecting the modes with smallest eigenvalues, one expects that the gauge fixed configurations are again smooth in the above sense.

To illustrate this we shall first consider pure gauge configurations, $U_\mu(x) = g(x)g(x + \hat{\mu})^\dagger$. Here the Landau gauge fixing condition has the solution $U_\mu^\Omega(x) = 1$. The eigenfunctions of the laplacian are gauge transforms of plane waves,

$$\begin{aligned} f(x)_a^s &= g(x)^{ab} \exp(ikx), \\ \lambda^s &= \sum_\mu (2\sin(k_\mu/2))^2, \end{aligned} \tag{11}$$

where the lattice volume is $V = N^4$ and the momenta are $k_\mu = 2\pi n_\mu/N$, $n_\mu = 0, \dots, N-1$. The label s is such that $s = 1, \dots, n$ corresponds to the n zero momentum modes. For

the pure gauge case the construction of Ω_Δ is simple and one finds

$$\Omega_\Delta(x) = \Omega_0 g(x)^\dagger, \quad (12)$$

where Ω_0 is a global $SU(n)$ transformation which is not specified by our construction. Note that these are precisely the gauge transformations that fix U to the Landau gauge.

Since the space dependence of the eigenfunctions for this simple case comes in as a $U(1)$ factor which drops out in the reduction to $SU(n)$ we cannot illustrate the importance of taking the low eigenvalue modes here. With $g \in U(n)$, however, our construction gives $\Omega_\Delta(x) = \Omega_0 g(x)^\dagger \exp(ikx)$, if eigenfunctions with momentum label k are used. Only for $k = 0$ this corresponds to the Landau gauge, for $|k| > 0$ the gauge fixed configuration is less smooth.

To elucidate the generic case, we consider the function

$$E(f) := \sum_{x,y} f(x)_a^\dagger \Delta(U)(x,y)^{ab} f(y)_b \quad (13)$$

Minimalizing E under the constraint that $\sum_x f(x)_a^\dagger f(x)_a^t = V\delta^{st}$ provides the eigenfunctions of $\Delta(U)$ as solutions (normalized to the volume V). After substituting the decomposition (9) in (13) one finds

$$\sum_a \lambda^a = 2n \text{Re} \sum_{x,\mu} \left[1 - \frac{1}{n} \text{tr}(e^{i\alpha(x)} P(x) \Omega_\Delta(x) U_\mu(x) \Omega_\Delta(x + \hat{\mu})^\dagger P(x + \hat{\mu}) e^{-i\alpha(x+\hat{\mu})}) \right] \quad (14)$$

This leads one to consider a modified Landau function R_Δ ,

$$R_\Delta(U^\Omega) = \text{Re} \sum_{x,\mu} \left[1 - \frac{1}{n} \text{tr}(W_\mu(x) \Omega(x) U_\mu(x) \Omega(x + \hat{\mu})^\dagger) \right]. \quad (15)$$

The weight function $W_\mu(x)$ is gauge invariant and follows from the eigenfunction construction,

$$W_\mu(x) = P(x + \hat{\mu}) P(x) e^{i(\alpha(x) - \alpha(x+\hat{\mu}))}. \quad (16)$$

The minimum of R_Δ over gauge orbits Ω is assumed for $\Omega = \Omega_\Delta$, coming from the eigenfunction construction: $R_\Delta^{\min} = \sum_{a=1}^n \lambda_a / 2n$. The weight function $W_\mu(x)$ is a function of all gauge links $U_\mu(x)$ and in this sense our gauge condition is non-local. Clearly R_Δ reduces to the (local) Landau function (1) if $W_\mu(x)_{ab} \rightarrow \delta_{ab}$.

This shows that our laplacian gauge condition corresponds to finding the absolute minimum of a modified Landau function (15). Trying to find the absolute minimum of R_Δ for a fixed $W_\mu(x)$ is practically impossible, but by using the $W_\mu(x)$ which follows from the eigenfunction construction, the problem is easily solved.

Discussion

We have shown that a smooth gauge, similar to the Landau gauge, can be defined unambiguously on the lattice, except for configurations which have measure zero in configuration space. In order to find it for gauge group $SU(n)$ or $U(n)$, one needs to

compute the eigenfunctions corresponding to the n smallest eigenvalues of the covariant lattice laplacian and make the reduction (9) to $SU(n)$ or $U(n)$ matrices. The time consuming part is the computation of the n lowest eigenfunctions. They can be computed with the Lanczos algorithm, or they can be found by inverse iteration (see e.g [12]), after the n eigenvalues have been computed with the Lanczos algorithm. Since the laplacian is hermitian, this should be feasible even on large lattices.

The main virtue of our gauge fixing procedure is the possibility to uniquely specify a smooth Landau-like gauge in non-perturbative lattice computations without breaking global symmetries like rotation invariance. At present it is not clear (to us) if laplacian gauge fixing can also be used in perturbation theory. Even if this is not possible, laplacian gauge fixed fields may be useful in the construction of improved hadron or glueball operators. For this purpose the Wuppertal group [14] has used the inverse covariant laplacian before, which is reminiscent of our approach. A construction based on laplacian gauge fixing, however, offers the possibility to interpret results physically in terms of gauge fixed quark and gluon fields.
